Abstract

In this work, an estimation of the reinforcement factor $\xi$ of the Halpin-Tsai equations used to calculate the transverse stiffness $E_2$ is provided. A better estimation of the value $\xi = 2$ originally suggested by Halpin and Tsai is given through a set of finite element analyses that consider randomly distributed unidirectional fibers for different volume fractions. The analysis overcomes the original hypothesis of a square array distribution of fibers in the transverse plane. It is concluded that a value of $\xi = 1.5$ is a better estimation for the usual volume fractions found in practice for a unidirectional lamina of fiber reinforced composites.

1. Introduction

The Halpin-Tsai equations [1] are widely used to calculate elastic properties of different configurations of composite materials. Among these properties, one of the most relevant is the transverse stiffness $E_2$ of a unidirectional lamina with oriented continuous fibers. It is well known that approaches based on a strength of materials analysis underestimate the true value of $E_2$, leading to a lower bound of $E_2$ (Reuss boundary) [2]. In the past a large number of models have been proposed in the literature to obtain more accurate estimations for $E_2$ and other elastic constants, many based in formal approaches of the theory of elasticity (see the excellent reviews in [1, 2]). These models account for the matrix-dominant effect on the homogenized value $E_2$ for a lamina, such as the Ekvall model [2] that considers the triaxial stress state in the matrix due to fiber restraint.

It has been extensively verified that the Halpin-Tsai (H-T) equations are a good practical way for calculating $E_2$, using the originally proposed value of the reinforcement factor $\xi = 2$. The wide application of the H-T equations heavily relies on their simplicity, which is desirable for design purposes. The reinforcement factor $\xi$ varies with the geometry of the reinforcement, its distribution and the volume fraction. Originally, the value of $\xi$ for oriented continuous fibers was derived by Halpin and Tsai from correlation with analytical solutions that assume an idealized geometrical distribution or pattern (e.g. Adams and Doner solution for a square array of fibers solved by a finite-difference scheme). Some approximate equations for $\xi$ are also given in the
literature to modify the value of $\xi$ for high volume fractions, as recalled in Section 2.

A question arises about the influence of a random distribution of the reinforcement in the transverse plane 2-3, which is much more realistic than a mere square arrangement. Since $\xi$ takes into account the effect of the geometry and distribution of the reinforcement, it is expected that this random distribution may have a non negligible effect. In this work, we carry out a series of parametric finite element analysis with different random distributions of fibers of circular cross section to quantify the influence of the random distribution. Several volume fractions are considered and the diameter of the fiber cross section is also varied randomly between the usual ranges.

An inverse analysis enables the estimation of $\xi$ for different volume fractions, leading to the conclusion that a more convenient value of $\xi$ is about 1.5 for typical volume fractions instead of the typical value of 2.0 derived from an idealized square arrangement and usually found in the literature. An important deviation is also found for low and high volume fractions.

2. Calculation of $E_2$ using the Halpin-Tsai equations

The H-T equations were developed in the late sixties [3] with the aim of providing a simple but an effective way of calculating the elastic properties of a fiber reinforced lamina, since previous developments led to complicated equations difficult to use. Halpin and Tsai developed an interpolation procedure attempting to gather the main results of those micromechanics analyses. The success of the H-T equations is based both on their simplicity and on the generalization of previous micromechanics results cumbersome to use, together with the relatively accurate estimations that provide for usual volume fractions. Thus, these equations are often termed as semiempirical [4], as they are based on mechanical fundamentals.

The H-T equations can be found in many books on mechanical behaviour of composite materials [1, 2, 4, 5]. The H-T equation for the transverse modulus $E_2$ is:

$$\frac{E_2}{E_m} = \frac{1 + \xi \eta V_f}{1 - \eta V_f}$$  \hspace{1cm} (1)

where

$$\eta = \frac{E_f/E_m - 1}{E_f/E_m + \xi}$$  \hspace{1cm} (2)

being $E_f$, $E_m$ the fiber and matrix modulus, respectively, and $\xi$ is the reinforcement parameter, which is the parameter estimated in this work. Analogous equations are formulated for $G_{12}$ and $\nu_{23}$. For the longitudinal modulus $E_1$ and $\nu_{12}$ the well-known rule of mixtures holds [1]. The only difficulty in using the Halpin-Tsai equations seems to be the determination of a suitable value for $\xi$. Halpin and Tsai proposed a value of $\xi = 2$ for calculation of $E_2$ and $\xi = 1$ for calculation of $G_{12}$ after obtaining an excellent agreement with Adams and Doner’s results for circular fibers in a square array at a fiber volume fraction of 0.55.

The reinforcement parameter $\xi$ depends on the fiber geometry, fiber distribution and loading conditions. It can be shown [2] that when $\xi = 0$ Eq. (1) reduces to the lower bound for $E_2$ given by a strength of materials approach, whereas when $\xi = \infty$ the rule of mixtures for $E_1$ is recovered (the theoretical upper bound for $E_2$). Thus, it is said that $\xi$ is a measure of the degree of matrix reinforcement by the fibers.
For high $V_f$, the constant value of $\xi = 2$ does not provide good results for $E_2$ and modifying equations have been proposed. For example, for $V_f \geq 0.65$, Hewitt and de Malherbe [6] suggested an equation for $\xi$ that provides better agreement with analytical results. For the case of $E_2$, this equation is [1]:

$$\xi(V_f) = 2 + 40V_f^{10}$$ \hspace{1cm} (3)

The H-T equations are also applicable to other reinforcement geometries, such as ribbon or particulate reinforcements. In [1], a comprehensive summary of $\xi$ values for other reinforcement geometries is given.

Since it is accepted that the values of $\xi$ are obtained by comparing (1) with exact elasticity solutions by fitting procedures [1, 2], the aim of this work is to estimate the value of $\xi$ with the elastic solutions provided by finite element analyses. Given that these analyses take into account the geometric effect of the random distribution of fibers in the plane 2-3 and also the variations in fiber diameter that are found in practice, it is expected that the estimations for $\xi$ will be more accurate than the current available values.

3. Calculation of $E_2$ and $\xi$ using finite element models

In order to estimate a better value for $\xi$ to calculate $E_2$, numerical models of the unidirectional fiber reinforced composite have been realized by means the finite element method. We consider a fiber-oriented coordinate system (1, 2, 3), being the 1-axis aligned with the fiber direction. The cross section analyzed in this work belongs to the 2 - 3 plane, as shown in Fig. 1. We assume a plane strain condition for the stress state at a given cross section, due to the longitudinal stiffness provided by the fibers.

Figure 1. Cross section in plane 2 - 3 and sketch of the domain analyzed numerically. A uniaxial uniform strain $\varepsilon_2 = \Delta L_2/L_2$ is applied. Symmetry boundary conditions are considered.

The domain is subjected to uniaxial uniform strain in direction 2 by enforcing a given displacement for the right boundary, i.e. $\varepsilon_2 = \Delta L_2/L_2$, see Fig.1. Symmetry boundary conditions have been considered, which is equivalent to consider a domain which is four times the domain actually analyzed. Three arrangements of fibers have been considered: square array, hexagonal array and random distribution, as described in Section 4.
3.1. Calculation of $E_2$

By assuming a linear elastic behavior, the generalized Hooke’s law in terms of the compliance matrix $S$ for an orthotropic lamina is:

$$
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
\varepsilon_{33} \\
\gamma_{23} \\
\gamma_{31} \\
\gamma_{12}
\end{pmatrix} =
\begin{pmatrix}
S_{11} & S_{12} & S_{13} & 0 & 0 & 0 \\
S_{12} & S_{22} & S_{23} & 0 & 0 & 0 \\
S_{13} & S_{23} & S_{33} & 0 & 0 & 0 \\
0 & 0 & 0 & S_{44} & 0 & 0 \\
0 & 0 & 0 & 0 & S_{55} & 0 \\
0 & 0 & 0 & 0 & 0 & S_{66}
\end{pmatrix}
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
\sigma_{33} \\
\tau_{23} \\
\tau_{31} \\
\tau_{12}
\end{pmatrix}
$$

(4)

As only a uniform strain in direction 2 is applied, the global equilibrium implies that $\sigma_{33} = 0$ and $\tau_{23} = 0$ due to the symmetry of the solution. Additionally, the plane strain condition implies that $\varepsilon_{11} = 0$, $\gamma_{31} = 0$ and $\gamma_{12} = 0$. Therefore, the strain-strain relationship (4) can be reduced to

$$
\begin{pmatrix}
\varepsilon_{11} \\
\varepsilon_{22} \\
\varepsilon_{33}
\end{pmatrix} =
\begin{pmatrix}
S_{11} & S_{12} & S_{13} \\
S_{12} & S_{22} & S_{23} \\
S_{13} & S_{23} & S_{33}
\end{pmatrix}
\begin{pmatrix}
\sigma_{11} \\
\sigma_{22} \\
0
\end{pmatrix}
$$

(5)

From the first equation of 5, it is clear that:

$$
\sigma_{11} = -\frac{S_{12}}{S_{11}}\sigma_{22}
$$

(6)

Recalling the symmetry of the compliance matrix $S$ and expressing its components in terms of engineering elastic constants:

$$
\sigma_{11} = -\frac{\nu_{12}/E_1}{1/E_1}\sigma_{22} = \nu_{12}\sigma_{22}
$$

(7)

and substituting this result in the second equation:

$$
\varepsilon_{22} = \left(1 - \frac{\nu_{12}^2}{E_2}ight)\sigma_{22}
$$

(8)

From this equation, an explicit expression for $E_2$ under a plane strain assumption can be obtained:

$$
E_2 = \frac{E_1\sigma_{22}}{E_1\varepsilon_{22} + \nu_{12}^2\sigma_{22}}
$$

(9)

The equation (9) is used to estimate $E_2$ from the numerical analysis, since $\varepsilon_{22}$ is the applied uniform strain $\Delta L_2/L_2$ and $\sigma_{22}$ is computed simply as the summation of the reaction forces at the right boundary divided by the net section at that boundary (we have assumed unit thickness). On the other hand, $E_1$ and $\nu_{12}$ are obtained from the constituents properties through the rule of mixtures, which holds for $E_1$ and $\nu_{12}$ as part of the H-T equations [1]:

$$
E_1 = E_iV_i + E_m(1 - V_i)
$$

(10)

$$
\nu_{12} = \nu_iV_i + \nu_m(1 - V_i)
$$

(11)
3.2. Calculation of $\xi$

For the computation of $\xi$, the value of $E_2$ is first calculated through (9) and introduced in equation (1). Then, an iterative procedure is used to solve simultaneously (1) and (2) for $\xi$ and $\eta$ until the solution converges.

4. Finite element analyses and results

The analyses have been performed with the finite element commercial code Ansys™. The 2D models have been meshed with quadratic triangular elements (see Fig. 2) and the fiber cross-section is circular for all cases. Both matrix and fibers have been considered isotropic and perfectly connected through their interfaces. In order to perform the analyses and compute $E_2$ and $\xi$, some material properties have been fixed as follows: $E_f = 250$ GPa, $\nu_f = 0.30$, $E_m = 5$ GPa, $\nu_m = 0.38$, which correspond to typical values for carbon fiber and epoxy resin, respectively. However, the material properties are not relevant, since $\xi$ depends on the reinforcement geometry and distribution, but not on the material properties. This has been verified by making a sensitivity analysis to the material properties (changed to typical glass fiber and polyester resin composite with $E_f = 72$ GPa, $\nu_f = 0.25$, $E_m = 3.5$ GPa, $\nu_m = 0.37$). As expected, the obtained estimations for $\xi$ are virtually coincident.

4.1. Square and hexagonal arrays

The first set of analyses are performed for a square array of fibers. The aim of this section is to verify that the prediction of our numerical model and calculation procedure is in agreement with the H-T equation using the customary value of $\xi = 2$, fitted originally for the Adams and Doner’s analytical solution for a square array. A total of 14 analyses have been carried out for different fiber volume fractions, starting from $V_f = 0.05$ to $V_f = 0.7$ (nearly the maximum theoretical value for a square array) at increments of 0.05. Fig. 2, left, shows the FE model for the case $V_f = 0.4$. The geometrical models have been automatically generated by dedicated macros. All fibers are assumed to have the same diameter: 7.2 $\mu$m.

![Figure 2](image.png)

**Figure 2.** FE meshes for square and hexagonal arrays, case $V_f = 0.4$. Displacement boundary conditions are shown.

The results are shown in Fig. 3. The solid curve denoted as H-T refers in fact to the $\xi$ estimation
provided by Eq. (3), which reduces to $\xi = 2$ for a wide range of $V_f$. The estimation of $\xi$ using the square array numerical models leads to slightly lower values of $\xi$ specially for $V_f$ in the range [0.1, 0.5]. Note the good agreement between the square array numerical solution and the H-T solution in the range [0.50, 0.55], where it is reported that the H-T solution matches very well the Adams and Doner’s solution for a square array [1, 2]. This proves that our numerical model conveniently reproduces the expected solution when a square array of fibers is assumed.

![Figure 3](image-url)  
**Figure 3.** Comparison of $\xi$ values for standard H-T equation and for numerical estimations with square and hexagonal arrays.

Further sensitivity analyses have been carried out by varying the domain size. In addition, full 3D models with a square array have been also realized to avoid the 2D assumption of plane strain. In all cases, we have verified that our models and procedure are sufficiently accurate.

Models with an hexagonal array have been also analyzed, see Fig. 2 right. It is worth noting that the estimation of $\xi$ when an hexagonal array is considered (see Fig. 3) yields values that are remarkably lower than the ones provided by Eq. (3). As a true fiber distribution is neither a square nor hexagonal array, this motivated us to perform analyses with random distributions, as shown in next section.

4.2. Random distribution

The same procedure has been followed with models generated by a random distribution. The geometrical models have been generated by routines developed in Matlab. Fig. 4 shows three of the geometrical models for the cases $V_f = 0.2$, 0.4 and 0.6. Note that eventual contacting fibers are allowed, as actually expected.

In addition, we have also considered the random variation of the fiber diameter. Although small, this can have a certain amount of influence, since $\xi$ is a parameter that depends on the geometry of the reinforcement and its distribution. From some cross section micrographs available in the literature (e.g. [5]), we have measured the distribution of diameters and generated geometrical models that account for the diameter variation. In these random-distributed models, the previous diameter of 7.2 $\mu$m has been varied in the range [6.7, 7.7]$\mu$m, as can be noticed in Fig. 4. Note
also that the domain size is adjusted for each volume fraction so as to respect the fiber diameters, i.e. the domains in Fig. 4 are not to scale.

![Figure 4. Geometrical models. Random distributions for the cases $V_f = 0.2, 0.4$ and $0.6$.](image)

As the distribution of the fibers and diameters is now random, we have generated three models around each volume fraction in the range $[0.05, 0.6]$, at increments of 0.05. Note that it has not been possible to generate a geometrical model with $V_f > 0.65$ due to fiber packing issues, as may well happen in practice. Note also that for each random model, the actual $V_f$ has been measured after the model is generated and this leads to a slight scatter in the values of $V_f$ shown in Fig. 5. A total number of 39 random models have been analyzed.

![Figure 5. Comparison of $\xi$ values for standard H-T equation and for numerical estimations with square array, hexagonal array and random distribution.](image)

The results in Fig. 5 show that the estimated values of $\xi$ lie below the ones provided by (3) and between the values obtained for square and hexagonal arrays. As shown in Fig. 5, a value of $\xi = 1.5$ seems to be more appropriate for volume fraction in the range $[0.25, 0.55]$ than the customary value $\xi = 2$. This new value of $\xi$ is proposed to compute $E_2$ through H-T equations, without compromising the advantages of these equations as far as simplicity is concerned.
5. Conclusions

The H-T equations are often used in the design practice because of their simplicity when compared to analytical approaches. However, the estimations for $E_2$ using these equations strongly depend on the value of the reinforcement parameter $\xi$ which takes into account the geometry and spatial distribution of the reinforcement. It is common practice to use a value of $\xi = 2$ for calculation of $E_2$ using the H-T equations, despite this value was originally fitted to the solution for a square array provided by Adams and Doner. In this work, we have carried out finite element analyses taking into account a random distribution of the fibers and their diameters, which is more realistic than the theoretical square array distribution. The analysis procedure has been verified by first comparing the results for a square array distribution and several sensitivity analyses. As a result of the study, a new value of $\xi = 1.5$ has been proposed to compute $E_2$ through H-T equations in the range $V_f \in [0.25, 0.55]$, under the assumption that a random distribution is more representative than the original square array distribution.
